### Equipartition Theorem

**Equipartition theorem:** If the energy of a classical system is the sum of  $n$  quadratic terms, and the system is in contact with a heat reservoir at temperature  $T$ , then the mean energy of the system is given by  $\frac{1}{2}nk_B T$ .

This theorem, which applies to classical systems with continuous energy levels, expresses the fact that energy is ‘equally partitioned’ between all the separate modes of the system, each mode having a mean energy of precisely  $\frac{1}{2}k_B T$ .

**Dulong & Petit’s law:** The molar heat capacity of a crystal is  $3R$  regardless of the substance.

This law represents the classical (high temperature) limit of the heat capacity, which derives from three translational and three vibrational degrees of freedom.

**Einstein’s model for the heat capacity of a solid.** The measured heat capacity of solids deviates below the prediction of Dulong & Petit, and tends to zero as  $T$  tends to zero. Einstein assumed that all atoms vibrate at a single angular frequency  $\omega$ , and treated the system as  $3N$  independent, quantized, harmonic oscillators in 3D. Each oscillator has quantized energy levels  $E_n = (n + \frac{1}{2})\hbar\omega$ . In this model the expression for the molar heat capacity is

$$C_V = 3Nk_B(\Theta_E/T)^2 \frac{e^{\Theta_E/T}}{(e^{\Theta_E/T} - 1)^2}, \quad (1)$$

where  $\Theta_E = \hbar\omega/k_B$ .

The molar heat capacity  $C_p$  ( $\approx C_V$ ) of diamond (data points) compared with the curve calculated from the Einstein model eqn (1) with  $\Theta_E = 1325$  K. Note the units: 1 calorie (cal) = 4.2 J, so  $3R = 5.94$  cal K<sup>-1</sup> mol<sup>-1</sup>. The deviation from the theoretical curve at low temperature is due to the assumption that all atoms vibrate at the same frequency, which is not the case in reality. A refinement of the theory by P. Debye gives better agreement at low temperatures. This figure is adapted from Einstein’s original paper: A. Einstein, *Annalen der Physik*, **22** (1907) 180–190.
